Introduction

An accurate and systematic approach is required to evaluate, diagnose and resolve esthetic problems predictably. Tooth color is obviously essential for the final result, but esthetic treatment planning should never be limited to just shade improvements alone. The ultimate goal is the achievement of a pleasing smile architecture considering the proper proportion and relation according to established principles. Predictable osseointegration has taken the role of implant dentistry beyond the mere restoration of function for the compromised edentulous case to esthetic single tooth implant-supported restorations in the anterior region. Today, implants have become a viable treatment option for partial edentulism. However, to be preferred treatment choice, the implant-supported restoration should, cosmetically, be equal or surpass that of conventional fixed prosthesis. This necessitates developing an implant recipient site in both hard and soft tissue for optimal placement of the implant and emergence of the restoration. Implants should not be limited by the osseous topography, which can compromise the final restoration, but implant placement should rather be restoration driven. The increasing predictability and longevity of ceramic implant abutments offer a beneficial asset to cosmetic implant prosthodontics.

Implant placement and single-tooth restoration in the "esthetic zone" of the anterior maxilla can present restorative challenges due to its high visibility and influence on the facial appearance. Conventional titanium abutments, for example, can diminish porcelain translucency and often result in a darkened restoration with a bluish, metal shimmer at its margin. This results in a significant loss of esthetic quality and may contribute to an unsatisfactory treatment outcome, particularly for patients with a high smile line and thin soft tissue. A subsequent change in soft-tissue margins often lead to the visibility of titanium at the gingival margin. Although metal implant abutments have inherent esthetic disadvantages, they are most widely considered a standard treatment option for implant supported restorations. The art of looking naturally, however, has been perfected by ceramics. Their application in restorative dentistry has opened up a new era in esthetic tooth replacement. Improved material characteristics, complying with clinicians' and patients' increased demands for highly esthetic results, have contributed significantly to the development of a new generation of implant abutments made from zirconium-dioxide noted for their tooth-like colour, high load strength, tissue tolerability and intra-scalar design enhancement. Plaque accumulation on implant abutments induces an inflammatory reaction within the gingiva and alveolar mucosa in the same manner as around teeth. Bacterial infection has also been reported to be one of the possible reasons for implant failure. Peri-implantitis is a sub-gingival bacterial plaque-induced inflammation that leads to passive bone loss. Major adhesion affinities of bacteria have been reported for different materials, such as titanium, titanium alloy and ceramics. The degree of adhesion between bacteria and abutment depends on the abutment's and bacteria's free surface energy, the roughness of the surface, and the salivus's ionic conductivity. Recent studies by Scannavo et al. confirmed a 40% reduction in bacterial adhesion on zirconium-dioxide compared to titanium with comparable roughness. A comparative immunohistochemical evaluation of vascular growth factor, inflammatory infiltrate, proliferative activity expression and micro vessel density in peri-implant soft tissues surrounding titanium and zirconium-dioxide healing caps, revealed statistically decreased values for zirconium-dioxide. Consequently, zirconium actively contributes to peri-implant tissue protection. This poster summarizes a systematic restorative approach using a zirconium abutment in combination with a novel premanufactured coping system in partially edentulous patients. The prosthetic and laboratory procedures for an implant-supported single tooth replacement in the esthetic region are addressed and illustrated in a step-by-step approach.

Case Report

After osseointegration and stage-two soft tissue healing a zirconium-dioxide abutment (CERCON®, DENTSPLY Friadent, Manheim) was attached to an implant (XIVE®, DENTSPLY Friadent, Manheim) replacing the right lateral incisor. After placing the abutment, a test component to be intended as a premanufactured corresponding zirconium coping (CERCON® Cap test component not regularly available) was seated and an impression was taken for the fabrication of a master cast. The ceramic coping serves hereby as an impression transfer cap, to be picked-up directly with the impression. Before pouring the cast, the zirconium abutment was connected to an implant analogue and securely seated into the cap. No additional modifications were required and porcelain was applied directly to the ceramic coping to complete a full-ceramic crown. The coping served as the foundation for the porcelain applied by the laboratory to create the final restoration. No additional ceramic crown or wax-up is necessary. The full ceramic crown, based on the zirconium cap was delivered and subsequently luted with resin cement.

Conclusion

The initial clinical results indicate that the investigated zirconium restorative system allows an expedite and systematic treatment to resolve esthetic challenges with a premanufactured ceramic abutment/coping system in partially edentulous patients.
